Abstract: Unattended ground sensors (UGS) are widely used to monitor human activities, such as pedestrian motion and detection of intruders in a secure region. Efficacy of UGS systems is often limited by high false alarm rates, possibly due to inadequacies of the underlying algorithms and limitations of onboard computation. In this regard, this paper presents a wavelet-based method for target detection and classification. The proposed method has been validated on data sets of seismic and passive infrared sensors for target detection and classification, as well as for payload and movement type identification of the targets. The proposed method has the advantages of fast execution time and low memory requirements and is potentially well-suited for real-time implementation with onboard UGS systems.

Keywords: Feature Extraction, Passive Infrared Sensor, Seismic Sensor, Symbolic Dynamic Filtering, Target Detection and Classification.

I. INTRODUCTION

Unattended ground sensors (UGS) are widely used in industrial monitoring and military operations. Such UGS systems are usually lightweight devices that automatically monitor the local activities in-situ, and transfer target detection and classification reports to the processing center at a higher level of hierarchy. Commercially available UGS systems make use of multiple sensing modalities (e.g., acoustic, seismic, passive infrared, magnetic, electrostatic, and video). Efficacy of UGS systems is often limited by high false alarm rates because the onboard data processing algorithms may not be able to correctly discriminate different types of targets (e.g., humans from animals) [2]. Power consumption is a critical consideration in UGS systems. Therefore, power-efficient sensing modalities, low-power signal processing algorithms, and efficient methods for exchanging information between the UGS nodes are needed [3]. In the detection and classification problem at hand, the targets usually include human, vehicles and animals. For example, discriminating human footstep signals from other targets and noise sources is a challenging task, because the signal-to-noise ratio (SNR) of footsteps decreases rapidly with the distance between the sensor and the pedestrian.

Furthermore, the footstep signals may vary significantly for different people and environments. Often the weak and noise contaminated signatures of humans and light vehicles may not be clearly distinguishable from each other, in contrast to heavy vehicles that radiate loud signatures [4], [5]. Seismic sensors are widely used for personnel detection, because they are relatively less sensitive to Doppler effects and environment variations, as compared to acoustic sensors [6]. Current personnel detection methods, based on seismic signals, are classified into three categories, namely, time domain [7], frequency domain [4], [5], [8], and time-frequency domain [6], [9]–[11]. Generally, time-domain analysis may not be able to detect targets very accurately because of the interfering noise, complicated signal waveforms, and variations of the terrain [6]. On the other hand, accuracy of frequency domain methods may be degraded due to underlying non-stationary in the observed signal. Therefore, recent research has relied on time-frequency domain (e.g. wavelet transform-based) methods because of their de-noising and localization properties. Passive Infrared (PIR) sensors have been widely used in motion detectors, where the PIR signals are usually quantized into two states, i.e., “on” and “off”. PIR signals contain discriminative information in the time-frequency domain and are well-suited for UGS systems due to low power consumption. Although PIR sensors have been used for detection and localization of moving targets [12], similar efforts for target classification have not been apparently reported in open literature.

The work reported in this paper makes use of a wavelet based feature extraction method, called Symbolic Dynamic Filtering (SDF). The SDF-based feature extraction algorithm mitigates the noise by using wavelet analysis, captures the essential signatures of the original signals in the time-frequency domain, and generates robust low-dimensional...

feature vectors for pattern classification. This paper addresses the problem of target detection and classification using seismic and PIR sensors that monitor the infiltration of humans, light vehicles and domestic animals for border security. The major contributions of the paper are as follows:

1. Formulation of a hierarchical structure for target detection and classification.
2. Experimental validation of the SDF-based feature extraction method on seismic and PIR sensor data.

The paper is organized into five sections including the present one. Section II Problem Description and Tree Structure Formulation. Section III SDF-Based Feature Extraction Algorithm. Section IV describes the details of the proposed method and the results of field data analysis. The paper is concluded in Section V along with recommendations for future research.

II. PROBLEM DESCRIPTION AND TREE STRUCTURE FORMULATION

The problem at hand is to detect and classify different targets (e.g., humans and animals), where seismic and PIR sensors are used to capture the respective characteristic signatures. For example, in the movement of a human or an animal across the ground, oscillatory motions of the body appendages provide the respective characteristic signatures. The seismic and PIR sensor data, used in this analysis, were collected on multiple days from test fields on a wash (i.e., the dry bed of an intermittent creek) and at a choke point (i.e., a place where the targets are forced to go due to terrain difficulties). During multiple field tests, sensor data were collected for several scenarios that consisted of targets walking along an approximately 150 meters long trail, and returning along the same trail to the starting point. Fig. 1 illustrates a typical data collection scenario.

Fig.1. Illustration of the test scenario with three sensor sites

The targets consisted of people (e.g., male and female humans) and animals (e.g., donkeys, mules, and horses). The humans walked alone and in groups with and without backpacks; the animals were led by their human handlers and they made runs with and without payloads. There were three sensor sites, each equipped with acoustic and seismic sensors. The seismic sensors were buried approximately 15 cm deep underneath the soil surface, and the PIR sensors were collocated with the respective seismic sensors. All targets passed by the sensor sites at a distance of approximately 5 m. Signals from both sensors were acquired at a sampling frequency of 10 kHz.

The tree structure in Fig. 2 shows how the detection and classification problem is formulated. In the detection stage, the pattern classifier detects the presence of a moving target against the null hypothesis of no target present; in the classification stage, the pattern classifier discriminates among different targets. While the detection system should be robust to satisfy the specifications of false alarm rates, the classification system must be sufficiently sensitive to discriminate between different classes of targets with high fidelity. In this context, feature extraction plays an important role in target detection and classification, because the performance of the classifier largely depends on the quality of the extracted features.

III. SDF-BASED FEATURE EXTRACTION ALGORITHM

The details of SDF briefly review the underlying concepts of feature extraction from sensor time series for completeness of this paper.

A. Transformation of Time Series to Wavelet Domain

A crucial step in SDF is partitioning of the transformed data space for symbol sequence generation. In wavelet-based partitioning, the time series is first transformed as a set of wavelet coefficients at different time shifts and scales, where the choice of the wavelet basis function depends on the time frequency characteristics of the underlying signal, and the (finitely many) wavelet scales are calculated as follows:

$$\alpha_{i} = \frac{F_{c}}{f_{i}^{p_{d}}}$$  \hspace{1cm} (1)

Where $F_{c}$ is the center frequency that has the maximum modulus in the Fourier transform of the signal; and $f_{i}$’s are

Fig.2. Tree structure formulation of the detection & classification problem

Volume.03, IssueNo.39, November-2014, Pages: 7877-7886
obtained by choosing the locally dominant frequencies in the Fourier transform. Fig.3 shows an illustrative example of transformation of the time series. The amplitudes of the wavelet coefficients over the scale-shift domain are plotted as a surface. Subsequently, symbolization of this wavelet surface leads to the formation of a symbolic image.

\[ \varphi(o_l|o_k) = \frac{N(o_l|o_k)}{\sum_{k'=1}^{K} N(o_l|o_{k'})} \quad \forall o_l, o_k \in O \]  

Where \( N(o_l, o_k) \) is the total count of events when \( o_k \) occurs adjacent to \( o_l \) in the direction of motion. The calculation of these transition probabilities follows the principle of sliding block code. A transition from the state \( o_l \) to the state \( o_k \) occurs if \( o_k \) lies adjacent to \( o_l \) in the positive direction of motion. Therefore, for every state on the state image, all state-to-state transitions are counted.

IV. RESULTS OF FIELD DATA ANALYSIS

Field data were collected in the scenario illustrated in Fig. 1. Multiple experiments were made to collect data sets of all three classes, i.e., human, vehicle and animal. The data were collected over three days at different sites. A brief summary is given in Table I showing the number of runs of each class. Each data set, acquired at a sampling frequency of 10 kHz, has \( 1 \times 10^5 \) data points that correspond to 10 seconds of the experimentation time. In order to test the capability of the proposed algorithm for target detection, another data set was collected with no target present. The problem of target detection is then formulated as a binary pattern classification, where no target present corresponds to one class, and target present (i.e., human, vehicle or animal) corresponds to the other class. The data sets, collected by the channel of seismic sensors that are orthogonal to the ground surface and the PIR sensors that are collocated with the seismic sensors, are used for target detection and classification. For computational efficiency, the data were down sampled by a factor of 10 with no apparent loss of information. Fig.4 depicts the flow chart of the proposed detection and classification algorithm that is constructed based on the theories of symbolic dynamic filtering (SDF) and support vector machines (SVM). The proposed algorithm consists of four main steps, namely, signal preprocessing, feature extraction, detection, and classification, as shown in Fig.4.

In the signal conditioning step, the DC component (i.e., the constant offset) of a seismic signal is eliminated by subtracting the average value and the resulting (zero-mean) signal is normalized to unit-variance with division by its standard deviation. The rationale for normalization to unit variance is to make pattern classification independent of the signal amplitude and any discrimination should be solely texture-dependent. For example, the amplitude of the seismic signal of an animal with a heavy payload walking far away could be comparable to that of a pedestrian passing by at a closer distance, although these two signals are of different texture. However, for PIR signals, only the DC component is
removed and the normalization is not carried out because the range of the PIR signals is not changed during the field test experiments.

In the feature extraction step, SDF captures the signatures of the preprocessed sensor time-series for representation as low dimensional feature vectors. Based on the spectral analysis of the ensemble of seismic data at hand, a series of pseudo frequencies from the 1-20 Hz bands have been chosen to generate the scales for wavelet transform, because these bands contain a very large part of the footstep energy [9]. Similarly, a series of pseudo-frequencies from the 0.2-2.0 Hz bands have been chosen for PIR signals to generate the scales. Upon generation of the scales, continuous wavelet transforms (CWT) are performed with an appropriate wavelet basis function on the seismic and PIR signals. The wavelet basis $db7$ is used for seismic signals since it matches the impulsive shape of seismic signals very well, and $db1$ is used for the PIR case since PIR signals are close to square waves. A maximum-entropy wavelet surface partitioning is then performed. Selection of the alphabet size $|\Sigma|$ depends on the characteristics of the signal; while a small alphabet is robust against noise and environmental variations, a large alphabet has more discriminate power for identifying different objects. The same alphabet is used for both target detection and classification. The issues of optimization of the alphabet size and data set partitioning are not addressed in this paper. Subsequently, the extracted low-dimensional patterns are used for target detection and classification. One pattern is generated from each experiment, and the training patterns are used to generate the separating hyper plane in SVM.

A. Performance Assessment using Seismic Data

This section presents the classification results using the patterns extracted from seismic signals using SDF. The leave one-out cross-validation method has been used in the performance assessment of seismic data. Since the seismic sensors are not site-independent, they require partial information of the test site, which is obtained from the training set in the cross-validation. Results of target detection and classification, movement type and target payload identification are reported in this section.

1. Target Detection and Classification: Fig.5 shows the normalized seismic sensor signals (top row) and the corresponding feature vectors (bottom row) extracted by SDF of the three classes of targets and the no target case. In the top row of Fig.5, the unit of the ordinate axes is dimensionless due to normalization of the seismic signals, where the original data were recorded in the unit of volt by microphones for storage in a digitized format. Each feature vector in the bottom row of Fig. 5 consists of 8 elements since the alphabet size $|\Sigma| = 8$.

and the sum of all the elements in each feature vector is 1. It is observed that the feature vectors are quite different among no target, vehicle and human/animal case. The feature vectors of human and animal are similar and yet still distinguishable. In the feature vector plots in Fig.5, the states with small index number correspond to the wavelet coefficients with large values, and vice versa.

For the purpose of comparative evaluation, kurtosis analysis [7], a benchmarking technique of footstep detection, is also used for target detection and classification. Kurtosis analysis is useful for footstep detection because the kurtosis value is much higher in the presence of impulsive events (i.e., target present) than the case of no target [7]. The results of SDF and kurtosis analysis are shown in Table II using confusion matrices, where the rows are the actual classes and the columns are the predicted classes. Similar notations are followed in the sequel in Tables IV, V, and VI. The shaded area in Table II represents the confusion matrices of target classification. The detection and classification accuracy is summarized in Table III. It is observed kurtosis analysis has slightly worse but comparable performance with SDF in target detection and vehicle classification, whereas SDF outperforms kurtosis analysis in distinguishing human from animal.

The execution of the MATLAB code takes 2.27 seconds and 43.73 MB of memory for SDF and SVM on a desktop computer to process a data set of $1 \times 10^4$ points and perform pattern classification with the following parameters: alphabet size $|\Sigma| = 8$, number of scales $|\alpha| = 4$, window size $l \times l = 2 \times 2$, number of most probable symbol $m = 1$, and quadratic kernel for SVM. Pattern classification consumes about 80% of the total execution time because by using leave-one-out cross-validation, the pattern classifier needs to be trained with all the remaining patterns (e.g., 235 in detection stage). The choice of quadratic kernel in SVM improves the performance of the classifier; however, it also increases the computation in training the classifier. It is expected the execution time and memory will be reduced significantly if fewer training patterns are used.

TABLE VI. Confusion matrix of the Three-Way Cross-Validation

Fig.6. Examples of seismic sensor measurements (top) and the corresponding feature vectors extracted by SDF (bottom) for human walking and running. (a) Walking. (b) Running.
2. Movement Type Identification: Upon recognition of human, more information can be derived by performing another binary classification to identify whether the human is running or walking. The physical explanations are: i) the cadence (i.e., interval between events) of human walking is usually larger than the cadence of human running; ii) the impact of running on the ground is much stronger than that of walking, and it takes longer for the oscillation to decay. Fig. 6 shows the seismic signal and corresponding feature vectors of human walking and running. The feature vectors of human walking and running are very different from each other, which is a clear indication that the SDF-based feature extraction method is able to capture these features (cadence and impact). It is noted that the feature vectors shown in Fig. 6 are different from those in Fig. 5 because different partitions are used in the target classification and movement type identification stages.

Ideally, the identification of movement type should be performed based on the results of human classification. However, in order to assess the performance of SDF in this particular application, a binary classification between human walking and human running is directly performed. The results are listed in Table IV, where the proposed feature extraction algorithm and SVM are able to identify the human movement type with an accuracy of about 91%. As stated as well as in earlier publications, the alphabet Σ in the SDF algorithm plays an important role for target detection and classification. An example illustrating the effects of the alphabet size |Σ| on human movement type identification is presented in Fig. 8, where the human movement type identification was performed with |Σ| varying from 2 to 20. It is seen that that the classification accuracy is consistent within the range of |Σ| from 2 to 20. The rationale is that the information loss increases with a smaller |Σ| and robustness to noise decreases with a larger |Σ|.

3. Target Payload Identification: Similar with the movement type identification shown above, the target payload information can also be derived by performing another binary classification for both animal and human targets. Fig. 7 shows the seismic signals and feature vectors of human/animal with and without payload examples. It is observed that the feature vectors extracted by SDF has large inter-class separation while small intra-class variance, and yet the intra-class differences between the with payload and without payload cases are still distinguishable. Table V shows the results of the human/animal payload identification. The shaded area in Table V represents the payload identification. It is seen that the proposed method is able to distinguish human from animal with high accuracy (97.3%). The payload identification result is also reasonable (human: 81.3%, animal: 79.1%); however, more than half samples in the human with payload and animal without payload cases are incorrectly classified. Three factors may contribute to low classification rate for these two classes: i) the payloads are not the same throughout all the experiments; ii) the weight of the payload is only a small fraction of the weight of human/animal target, so difference between the two classes (with payload/without payload) are not obvious; iii) Unbalanced number of samples in each class. The first two issues are related with data collection; the last issue may be resolved by increasing the weight of the class with fewer samples when generating the separating hyper plane in SVM.

B. Performance Assessment Using PIR Data
PIR sensors are widely used for motion detection. In most applications, the signals from PIR sensors are used as discrete variables (i.e., on or off). This may work for target detection, but will not work well for target classification because the time-frequency information is lost in the discretization. In this paper, the PIR signals are considered to be continuous signals, and continuous wavelet transform (CWT) is used to reveal the distinction among different types of targets in the time-frequency domain. Since a PIR sensor does not emit an
Trespasser Detection and Categorization using Unattended Ground Sensors (UGS)

Fig. 8. Effect of alphabet size on human movement type identification.

infrared beam but merely passively accepts incoming infrared radiation, it is less sensitive to environmental variations (i.e., variation in test sites) than the seismic sensor that is ground based. A three-way cross-validation is used for the performance assessment of PIR data. The data are divided into three sets by date (i.e., Day 1, Day 2, and Day 3) and three different sets of experiments are performed:

1. Training: Day 1 + Day 2; Testing: Day 3
2. Training: Day 1 + Day 3; Testing: Day 2

Training and testing on feature vectors from different days is very meaningful in practice. In each run of the cross-validation, no prior information is assumed for the testing site or the testing data. The classifiers’ capability to generalize to an independent data set is thoroughly tested in the three-way cross-validation. In this section, four types of targets are considered, namely, no target, human walking, human running, and animal led by human. Following Fig. 4, the following cases are tested:

1. Detection of target presence against target absence;
2. Classification of target type, i.e., Human vs. Animal;
3. Classification of target movement type (i.e., walking vs. running) upon recognition of the target as human.

Fig. 9 shows the PIR sensor measurements (top) and the corresponding feature vectors extracted by SDF (bottom) of the four classes. For the no target case, the PIR signal fluctuates around zero and no information is embedded in the wavelet coefficients, thus the states in the middle (i.e., states 3-10) are occupied; whereas for the target present cases, the PIR sensors are excited by the presence of the targets, so states 1-2 and 11-12 that correspond to the crests and troughs in the PIR signals are more populated than other states. The following parameters are used in SDF and SVM for processing the PIR signals: alphabet size $|\Sigma| = 12$, number of scales $|\alpha| = 3$, window size $l \times l = 2 \times 2$, number of most probable symbol $m = 1$, and quadratic kernel for SVM. The execution of SDF and SVM takes 1.13 seconds and 39.83 MB of memory on a desktop computer to process a data set of $1 \times 10^4$ points, which is a clear indication of the real-time implementation capability for onboard UGS systems.

Table VI shows the confusion matrix of the three-way cross-validation results using PIR sensors. The shaded area represents the target classification stage. It is seen in Table VI that the proposed feature extraction algorithm works very well with the PIR sensor; the target detection accuracy is 99.5%, the human/animal classification accuracy is 91.7%, and the human movement type classification accuracy is 79.3%. Leave-one-out cross-validation usually underestimates the error rate in generalization because more training samples are available; it is expected that the classification accuracy will further improve for the PIR signals if leave-one-out cross-validation is used.

C. Field Deployment of Seismic and PIR Sensors

Seismic and PIR sensors have their own advantages and disadvantages for target detection and classification. The seismic sensor is omnidirectional and has a long range of detection (up to 70m) [11], whereas a PIR sensor has a typical range of less than 6m and has a limited field of view (less than 180°), which restricts the sensor from detecting target moving behind it. The seismic sensor is not site-independent and is vulnerable to variations in sensor sites, whereas a PIR sensor merely passively accepts the incoming infrared radiation and is independent of the sensor site. In order to improve the detection and classification accuracy while reducing the false alarm rate, it is recommended that the seismic and PIR sensor should be used together to provide complementary information to each other. Information fusion techniques are needed to combine the outputs of the two sensing modalities, and this is a topic of future research.

Field deployment of sensors largely depends on the tasks and terrains. To enhance the perimeter security [8] in an open field, the sensors are usually deployed linearly or in circles. Since the intruder may approach the secure region from any direction, the worst case scenario is when the intruder approaches the secure region exactly half-way between two adjacent sensors along a straight path perpendicular to the sensor picket line. To ensure intruder detection, the maximum sensor spacing should be less than the effective range of the sensor. Therefore, sensor deployment could be very expensive, because the detection range of PIR sensors is less than 6m. Another critical application is sensor deployment at choke points; since the targets are forced to pass the choke point due to the terrain difficulties, a single node of UGS system can be sufficient to cover the entire region.

V. CONCLUSION

This paper presents a symbolic feature extraction method for target detection and classification, where the features are extracted as statistical patterns by symbolic dynamic modeling of the wavelet coefficients generated from time series of seismic and PIR sensors. By appropriate selection of wavelet basis and scale range, the wavelet-transformed signal is de-noised relative to the original time-domain signal. In this way, the symbolic images generated from wavelet coefficients capture the signal characteristics with larger fidelity than those obtained directly from the time domain signal. The symbolic images are then modeled using probabilistic finite state automata (PFSA) that, in turn, generate low-dimensional statistical patterns, also called feature vectors. A distinct advantage of the proposed feature extraction method is that the low-dimensional feature vectors can be computed in-situ and communicated in real time over a limited-bandwidth wireless sensor network with limited-memory nodes. The proposed method has been validated on a set of field data collected from different locations on multiple days. A comparative evaluation is performed on the seismic signals between SDF and kurtosis analysis using leave-one-out cross validation. Results show that SDF has superior performance over kurtosis analysis, especially in the human/animal classification.

In addition, the capabilities for identifying movement type and target payload are examined for the seismic sensor. A three-way cross-validation has been used to assess the performance of PIR sensors for target detection and classification. Results show that PIR sensors are very good for target detection, and have comparable performance with seismic sensors for target classification and movement type identification. While there are many research issues that need to resolve before exploring commercial applications of the proposed method, the following topics are under active research:

1. Enhancement of target detection and classification performance by fusion of seismic and PIR sensor signals.
2. Real-time field implementation of the proposed method on low-cost low-power microprocessors for different types of deployment (e.g., UGS fencing to secure a region).
